A Dynamic Measurement Technique for Third Order Distortion in Optical Phase Modulators

Matthew N. Sysak, Member, IEEE, Leif Johansson, Member IEEE, Jonathan S. Klamkin, Student Member, IEEE, John E Bowers, Fellow, IEEE.

Abstract—A novel two tone measurement technique for characterizing distortion in optical phase modulators is proposed and demonstrated. The technique is used to characterize an InGaAsP/InP modulator in a monolithically integrated receiver. Results for forward and reverse bias conditions in the modulator show a phase IP3 of 7.2π and 0.97π radians, respectively.

Index Terms—Phase modulators, phase distortion, carrier injection, Quantum Confined Stark effect (QCSE).

I. INTRODUCTION

Transmission systems that utilize optical phase modulation are attractive for both analog and digital communication links. In analog transmission applications, phase modulation is attractive since it is not limited by the zero and full rail levels in standard intensity modulated systems. For digital transmission links, phase modulated systems provide tolerance to fiber dispersion effects and wide wavelength transparency.

To evaluate the performance of various phase modulators, several characterization techniques have been employed. For static characterization, phase efficiency experiments can be performed using shifts in a Fabry-Perot cavity or by utilizing a Mach-Zehnder interferometer (MZI) [1,2]. However, dynamic distortion characterization of phase modulators has been limited to single tone measurements because nonlinearities in the phase detection process are difficult to separate from the nonlinearities produced by the modulator [3].

In this work we propose and demonstrate a two-tone measurement technique for characterizing the distortion generated by optical phase modulators that is not limited by the distortion in the phase recovery process. The technique relies on a linear external LiNbO3 phase modulator to cancel the fundamental response of the test modulator, keeping the phase to amplitude phase recovery process within the linear regime of an optical MZI. Cancellation of the fundamental response does not effect the third order distortion terms. Using this technique we have compared the linearity of an InGaAsP phase modulator under forward and reverse bias conditions that is part of an integrated InGaAsP/InP photonic receiver chip. The comparisons are based on a modulator phase IP3, where the distortion and fundamental phase response of the test device are equivalent.

II. EXPERIMENTAL SETUP

The experimental setup used in these measurements is shown in Fig 1. The setup is divided into electrical and optical sections. The optical portion consists of an optical transmitter, including a laser source at 1550 nm, an EDFA, and an optical filter that is split into two arms of a Mach-Zehnder interferometer (MZI) and then recombined in a balanced photodetector. Both arms of the MZI contain an external LiNbO3 modulator and a 500 μm long InGaAsP phase modulator that is part of the photonic receiver chip. Polarization controllers are utilized before and after each LiNbO3 modulator. The photonic chip contains two parallel waveguides, each with an integrated InGaAsP phase modulator, a 2x2 multi-mode interference (MMI) combiner, and a set of 100 μm long UTC-PDs placed in a balanced configuration [4]. The InGaAsP phase modulator (φ mod) in the lower arm of the MZI is used to bias the interferometer. The InGaAsP modulators utilize 7x6.5 nm quantum wells and 6x5 nm barriers with a photoluminescence peak of 1465 nm centered in an optical waveguide layer for phase efficiency.

The electrical portion of the test setup consists of two signal generators and a series of electrical splitters and combiners. The individual tones from each function generator are combined in a 2:1 combiner, then split into two electrical paths using a 1:2 splitter. The outputs from the splitter contain signal tones from both function generators. One of the outputs from the splitter is routed to the LiNbO3 modulator, while the second output is routed to the test modulator (φ mod). A set of attenuators are used to control the electrical power delivered to the modulators. A portion of the signal from the balanced detector is routed to a low frequency feedback circuit. The output from the circuit is connected to a second LiNbO3 modulator, which compensates low frequency drift in the test bed and forces the power difference at the output of the balanced detector to zero [5].

To ensure that the nonlinearities associated with the test equipment and the various splitters and combiners in the test bed are minimized, the two-tone electrical signal used to drive the LiNbO$_3$ and InGaAsP modulators was examined over a range of electrical powers. The drive signals contained no observable distortion for powers up to and exceeding the levels utilized in our experiments. To eliminate the possibility that distortion might be generated in the UTC-PDs, two-tone measurements were performed on a set of test devices with the same dimensions as the photodiodes in the receiver chip. Results showed an output power IP$^3$ of >+30 dBm for the 100x10 $\mu$m$^2$ UTC-PD at a bias of -5V [4].

The center frequency of the two-tone signal is chosen so that the path length difference between the 1:2 electrical splitter and the InGaAsP or LiNbO$_3$ modulator corresponds to a phase delay of an odd multiple of $\pi$ radians. To investigate the electrical delay between the two paths, the function generators and the 2:1 combiner were removed and a frequency response measurement was performed between the 1:2 splitter and the balanced UTC-photodetector. Results from this measurement are shown in Fig 2 when the InGaAsP modulator is forward biased. Dips in the response correspond to frequencies where the electrical path lengths are mismatched by an odd multiple of $\pi$ radians. Under these conditions, the 180 degree phase lag between the signals to each modulator cause the phase response of the two devices to cancel. The roll off of the response in this measurement is a result of a low (~150 MHz) 3-dB bandwidth of the forward biased InGaAsP modulator [2].

### III. Measurement Technique

Characterization of the reverse and forward bias InGaAsP phase modulator requires a set of two experiments. All measurements are performed at an MZI bias where the average photocurrent in both UTC-PDs is 1.7 mA.

The first set of experiments examines the fundamental response of the test modulator. This experiment uses only the test InGaAsP modulator and does not utilize the LiNbO$_3$ modulator. The bias-T in the electrical path sets either forward or reverse bias conditions in the device. In this experiment, the power from the two electrical signal generators that is routed to the test device is varied and the output of the balanced detector has components associated primarily the fundamental response of the InGaAsP device. Since the LiNbO$_3$ modulator relies on the highly nonlinear quantum confined stark effect and plasma effect [7], the phase cancellation between these modulators affects primarily the fundamental response of the InGaAsP device while preserving modulator distortion products. The reduced fundamental permits the phase to amplitude conversion to remain in the linear regime of the MZI, preserving the distortion produced in the test modulator without adding distortion from the phase recovery process. A sample spectrum from the UTC-PDs in these experiments is shown in Fig 3 and labeled “Compensated Response.”

![Figure 2](image1.png)

**Fig. 2.** Frequency response measurements between the 1:2 splitter and the balanced UTC-PD. Nulls correspond to frequencies where the path length mismatches between the LiNbO$_3$ and InGaAsP modulators are separated by an odd multiple of $\pi$ radians.

**Fig. 3.** Compensated and uncompensated spectra for forward biased InGaAsP phase modulator. Electrical drive power is -15 dBm and 0 dBm to the InGaAsP and LiNbO$_3$ modulators respectively. The compensated spectra has not been optimize for maximum distortion suppression.

### IV. Results

Results for characterization of the forward biased InGaAsP modulator with a 10 mA DC bias are shown in Fig 4.

In the uncompensated measurements, Fig. 4 shows an input power IP$^3$ of +7.6 dBm. Using a modulator $V_n$ of 0.5V, this translates into a peak phase IP$^3$ of 1.5$\pi$ radians. The phase IP$^3$ can also be calculated based on the output power IP$^3$ in Fig 4. Based on the phase efficiency of 3.4 mA/radian in the balanced detector, this translates into a peak phase IP$^3$ of 0.45$\pi$ radians. Both results are in relatively good agreement with the 0.9$\pi$ peak phase limit that is associated with an optical MZI [6]. It should be noted that any RF losses at the detector or any deviation from the quadrature point in the test set up.
caused by imbalance coupler splitting reduces the output power IP3 in these measurements and would cause an artificially low phase IP3.

For the compensated measurements, the cancellation of the InGaAsP fundamental by ~33 dB leads to a suppression of the MZI nonlinearities and isolation of the modulator distortion. The corresponding reduction of the measured distortion is ~33 dB. It is important that although the fundamental phase response is reduced, it is not eliminated, and the compensated measurements are still limited by the theoretical phase IP3 of 0.9π associated with the MZI. The theoretical distortion generated by the test setup is included in Fig. 4 and labeled “compensated MZI distortion.” The experimental data in these measurements is >20 dB above the theoretical MZI distortion, indicating that the test bed nonlinearities have been sufficiently removed to expose the modulator distortion.

Combining the fundamental response in the uncompensated measurements with the third order response in the compensated measurements allows extraction of the forward biased modulator phase characteristics. From Fig. 4, the input power IP3 is +20.9 dBm, which corresponds to a phase IP3 of 7.2π. As mentioned previously, the output power IP3 can also be used to calculate phase IP3. The +10.85 dBm input power IP3 in Fig. 4 corresponds to a phase IP3 of 2.1π radians. However, the most accurate measure of the modulator performance is most likely the calculation of phase IP3 based on the input power. This is because the UTC-PD losses and MZI imbalance or bias offsets from quadrature reduce the RF power from the detector and make the phase IP3 appear artificially small.

Results for the reverse biased modulator characterization are shown in Fig. 5. The applied DC bias is -2V. Examining the distortion and fundamental tones in the uncompensated measurements shows an output and input power IP3 of -7.2 dBm and +24.7 dBm, respectively. Converting this to an output phase change gives 0.8π radians based input power IP3 (Vπ is 6.8V) and 0.25π radians based on the output power IP3. The phase IP3 based on the input power IP3 is in good agreement with the 0.9π that should limit the MZI, and indicates that the modulator distortion is roughly equal to the distortion generated by the test setup.

In the compensated measurements when the test bed nonlinearities are reduced, the very small (~3-4dB) reduction in the distortion data supports the conclusion that the modulator and test bed distortion are roughly equivalent. As in Fig. 4, the distortion associated with the MZI in the compensated measurements is included in Fig. 5, and is labeled “compensated MZI distortion.”

Extrapolating the fundamental response from the uncompensated measurements and the distortion in the compensated measurements gives input and output power IP3s +26.4 and -5.65 dBm, respectively. Converting the input power power IP3s to phase gives a phase IP3 for the reverse biased modulator of 0.97π radians.

V. CONCLUSIONS

We have proposed demonstrated a dynamic measurement technique for characterizing distortion products in optical phase modulators. The technique has been used to characterize the nonlinearities in an InGaAsP phase modulator under forward and reverse bias conditions. Measurements of the test modulator under forward and reverse bias conditions showed a phase IP3 of ~7.2π and 0.97π respectively.
